Abstract

In Japan due to the rapid population aging and its large financial pressure on pay-as-you-go retirement systems, the economic impact of bequest wealth has been drawing a tremendous amount of attention. Despite that, there are neither official statistics on bequest for the whole population nor analyses of the historical evolution of bequest. Our study fills this gap by offering an estimate of bequest in Japan from 1850 to 2100, based on a computable general equilibrium model with realistic demography. Our model shows that the historical evolution of the bequest-to-output ratio follows the same U-shaped pattern described by Piketty (2011) for France. Moreover, we estimate that the annual flow of bequest represented between 4\% and 6\% of output in the year 2000 and it is expected to reach between 7\% and 13\% of the output by year 2100.

*The authors are grateful to seminar participants at Nihon University Population Research Institute and the 9th meeting of the Working Group on Macroeconomic Aspects of Intergenerational Transfers (UB, Barcelona) for helpful comments. We have benefited from comments, suggestions, and ideas of Ronald Lee, Andrew Mason, Hidehiko Ichimura, and we have received helpful assistance from Junichi Sakamoto. Of course, any error are still our own.
1 Introduction

Historically, economic development in most countries has been accompanied by declines in total fertility rates, increases in life expectancy, especially at older ages, and population aging. These changes tend to affect a country’s economic growth, saving rates, and worker productivity. Moreover, these demographic trends place a large financial pressure on pay-as-you-go retirement systems, and impose a heavy burden on young and unborn cohorts. For this reason, it is central for policymakers to find new resources that reduce the negative economic consequences of population aging and maintain an intergenerational equilibrium.

An obvious candidate is the amount of wealth that is transferred to surviving individuals at death, i.e. bequest. In modern economies, economic growth comes from the accumulation of human and non-human capital. Unless the technological progress is high, a rapid population aging process leads to an inevitable decline in the accumulation of human capital. In contrast, assets can be passed from one generation to another. Also, these assets can be used by one cohort to compensate for the increasing fiscal burden of subsequent cohorts.

In this regard, Japan is an interesting and special case because Japan’s population aging has been the fastest in the world, and yet the labor force participation rates for older persons also remain among the highest among developed countries. Furthermore, in Japan, which is comparatively advanced in terms of policies regarding population aging, the economic impact of bequest wealth has been drawing a tremendous amount of attention. And yet, despite that, there are neither official statistics on bequest for the whole population nor analyses of the historical evolution of bequest.

Our study aims to fill this gap by offering an estimate of bequest in Japan from 1850 to 2100, based on a computable general equilibrium model (CGE) with realistic demography. Specifically, we create an economic model based on a real-life population structure, in which consumption/saving, labor supply (at the intensive and extensive margins), and bequest are determined endogenously. Furthermore, we demonstrate our model’s traceability comparing our bequest profiles to real bequest values obtained from the Japanese Study on Aging and Retirement (JSTAR) and consumption and labor profiles from the National Transfer Accounts project (NTA).

Since there were no surveys that ask about the amount of bequests that respondents received, previous studies have implemented different methods to overcome this problem. For example, following Kotlikoff and Summers (1981) Hayashi (1986), Dekle (1989) and Campbell (1997) calculated the bequest amount by deducting lifecycle wealth from household wealth. Barthold and Ito (1992) did an inverse calculation of the amount of taxable bequests based on inheritance tax statistics, while Shimono (1991) conducted a simulation analysis, and Shimono and Ishikawa (2002) estimated the proportion of bequests based on the scenario that males 65 and over die immediately. The downside of estimating bequest from the Japanese National Tax Agency’s data is that there are a lot of cases of tax exemption. In this paper, instead, we estimate the amount of bequest using the JSTAR. This database provides publicly accessible panel data on individuals between ages 50 to 75 in year 2007. JSTAR is similar to the Health and Retirement Study (HRS), the English Longitudinal Survey on Ageing (ELSA), and the Survey on Health, Aging and Retirement in Europe.
(SHARE). Hence, JSTAR contains a variety of variables comparable to those in HRS, ELSA, and SHARE (Ichimura et al., 2009). By using this survey we are able to estimate the bequest received between year 2007 and 2009. Unfortunately, the sample of people who have received bequest during the first two waves of this survey is only 216 cases out of 3946. Consequently, we have opted for running three alternative scenarios that we believe covers the most likely bequest profile for the reference year 2009.

The results obtained from our simulations show that the historical evolution of the bequest-to-output ratio follows the same U-shaped pattern described by Piketty (2011) for France. However, the most important component explaining the U-shaped pattern is the evolution of the crude death rate (i.e. the number of deaths relative to the total population during a given year), rather than the evolution of the capital-to-output ratio or the ratio between the average wealth of the deceased and the average wealth of the leaving. Second, we estimate that in the year 2000 the annual flow of bequest represented between 4% and 6% of output and it is expected to reach between 7% and 13% of the output by year 2100. Hence, if current bequest represents 50% of total inheritance like in France, the share of the annual flow of inheritance in the GDP is likely to be over 10% in current Japan. During the 21st century, unless individuals have a strong bequest motive, our simulation results show that the influence of bequest and labor income in shaping the accumulation of assets will be the same as in the second half of the 20th century.

The rest of the paper is organized as follows: Section 2 introduces the economic and demographic model setup. In Section 3 we present the economic and demographic data used to perform the calibration process. Also, we demonstrate that our model reproduces well the historical evolution of the capital-to-output ratio, consumption profiles, and labor income profiles for several years, and the per capita bequest by age in year 2009. In Section 4 we report our estimated evolution of the bequest from year 1850 to 2100. Section 5 is devoted to showing the distribution of per capita bequest during the period 1850-2100 and demonstrating the relationship between the distribution of bequest by age and the stock of capital. Concluding remarks are made in Section 6.

2 Model economy

2.1 Demographics

Time is discrete. Let \( t \in \mathcal{T} = \{t_0, t_0 + 1, \ldots, T\} \) denote time, where \( t_0 \) and \( T \) are the first and last years at which the population is compute. Individuals face mortality and fertility risk that differs by age and across cohorts. Lifetime uncertainty is represented by a standard survival probability function \( s_{i,x} \). Let \( p_{i,x} \) be the conditional probability of surviving to age \( x + 1 \) of an individual born in year \( i \) (with \( p_{i,x} = 0 \) for all \( x = \Omega \), where \( \Omega \) is the maximum age), and let \( q_{i,x} = 1 - p_{i,x} \) be conditional probability of dying between age \( x \) and \( x + 1 \). The probability that an individual born in year \( i \) survives at least to age \( x \), conditional on being alive at age 0, is given by

\[
s_{i,x} = \prod_{u=0}^{x-1} p_{i,u}, \quad \text{where} \quad p_{i,0} = 1.
\]
Let $N_t$ denote the total population size in year $t$ and $N_{t,x}$ be the size of the population at age $x$ in year $t$. We assume a closed population whose law of motion is given by

$$N_{t+1} = N_t + B_t - D_t.$$  

(2)

Population in year $t+1$ equals the population in year $t$ plus the total number of births in year $t$, denoted by $B_t$, minus the total number of deaths during the year $t$, or $D_t$. The dynamics of the population can also be written as a first-order Markov process using the Leslie matrix (Leslie, 1945):

$$N(t+1) = L(t)N(t),$$  

(3)

where $N(t)$ is a $\Omega \times 1$ vector that contains the population size by age in year $t$. $L$ is a matrix with structural zeros, except for the first row that contains the expected number of kids at the end of the period, i.e. $L_{1,x}(t) = \frac{1}{2} (f_{t-x,x} + f_{t-1,x} p_{t-x,x}) f_{fab}$, where $f_{t-x,x}$ is the age-specific fertility rate at age $x$ of an individual born in year $t - x$ and $f_{fab}$ is the standard value of the fraction of females at birth ($f_{fab} = 0.4886$), and the first sub-diagonal that contains the conditional survival probabilities, i.e. $L_{x+1,x}(t) = p_{t-x,x}$.

Households are comprised of two adults, or household heads, and dependent children. Notice that this assumption is necessary for a realistic distribution of bequest between offspring and the surviving spouse. For the sake of simplicity, we introduce the following demographic assumptions: i) individuals are paired at the onset of fertility with people of the same cohort (“married”); ii) exit from “marriage” only occurs because of death (“widowhood”); iii) bequest is given either to children, or spouse, or both; iv) children have two representative parents; and v) the burden of rearing children is equally distributed between both household heads, which are a commitment in terms of time and money to support their children consumption needs. Realize that from assumptions i) and ii), we can characterized the partnership status of an individual born in year $i$ and age $x$ according to a Markovian process of order one:

$$\begin{pmatrix} m_{i,x+1} \\ h_{i,x+1} \\ d_{i,x+1} \end{pmatrix} = \begin{pmatrix} p_{i,x} q_{i,x} & 0 & 0 \\ 2 q_{i,x} P_{i,x} & p_{i,x} & 0 \\ q_{i,x} q_{i,x} & q_{i,x} & 1 \end{pmatrix} \cdot \begin{pmatrix} m_{i,x} \\ h_{i,x} \\ d_{i,x} \end{pmatrix},$$  

(4)

where $m_{i,x}$ is the probability that both heads are married at age $x$, $h_{i,x}$ is the probability that one head is a widow/er at age $x$, and $d_{i,x}$ is the probability that both heads are dead at age $x$. The total time devoted to childrearing for a household head born in year $i$ at age $x$ is represented by $\eta_{i,x}^c$. The size of the household for each household head $\eta_{i,x}^c \geq 1$, which is expressed in units of equivalent adult consumers, takes into account the cost of the consumption needs of the children. Let $n_{i,x} = \{\eta_{i,x}^c, \eta_{i,x}^f\}$ be the set of both burden variables, which varies over time because of fertility and mortality and because children leave their parent’s home.

## 2.2 Firm

There is a neoclassical representative firm that combines capital and labor using a Cobb-Douglas constant returns to scale production function to produce a single good, which can either be saved or consumed,

$$Y_t = K_t^\alpha (\Gamma_t L_t)^{1-\alpha},$$  

(5)
where \( Y_t \) is output, \( K_t \) is the stock of capital, \( \alpha \) is the capital share, \( L_t \) is the effective aggregate labor input, and \( \Gamma_t \) is labor-augmenting technological progress, whose law of motion is \( \Gamma_{t+1} = (1 + g_t)\Gamma_t \). Aggregate capital stock evolves according to the law of motion:

\[
K_{t+1} = K_t(1 - \delta) + I_t,
\]

(6)

where \( \delta \) is the depreciation rate of capital and \( I_t \) is aggregate gross investment.

We assume our representative firm maximizes the net cash flow by renting capital and hiring labor from households in competitive markets at the rates \( r \) and \( w \), respectively. Then capital and skill-specific labor inputs are chosen by firms according to the first-order conditions:

\[
r_t + \delta = \alpha \left( \frac{Y_t}{K_t} \right),
\]

(7)

\[
(1 + (1 - \varsigma)\tau_{s,t})w_t = (1 - \alpha) \left( \frac{Y_t}{L_t} \right).
\]

(8)

where \((1 - \varsigma)\tau_{s,t}\) reflects the fraction of the social contribution paid by the employer.

### 2.3 Household’s problem

Households are comprised of either one adult (“widow/er”) or two adults (“marriage”), and a number of dependent children. Household heads equally share the duties and benefits of the household. Individuals become adults at age \( x_0 \), the moment at which they become financially independent and set up their own household.

Adults follow the life-cycle theory of labor supply (Heckman and MaCurdy, 1980, 1982) under mortality risks (Yaari, 1965), endogenous retirement decision (Sanchez-Romero et al., 2013), and bequest motive (Imrohoroglu and Kitao, 2012). The conditional expected utility function on retiring at age \( z \) for a household head born in year \( i \) at age \( x \) is

\[
V(a_{i,x_0}; z) = \sum_{x=x_0}^{\Omega-1} \left( \prod_{x=x_0}^{x} \beta p_{i,s} \right) \frac{u(c_{i,x}, \ell_{i,x}) + \beta q_{i,x+1}u^B(a_{i,x+1})}{\beta p_{i,x_0}},
\]

(9)

where \( \beta \) is the subjective discount factor, \( u \) is the period utility function (with \( u_c \geq 0, u_r \leq 0, u_{cf} \geq 0 \), and \( u_{cc}, u_{ff} \leq 0 \)), \( c_{i,x} \) is the consumption cost bore by one household head, and \( \ell_{i,x} \) is the work effort of an adult born in year \( i \) of age \( x \). \( u^B \) is the period utility from leaving bequest (with \( u^B_a \geq 0, u^B_{aa} \leq 0 \)), and \( a_{i,x} \) are asset holdings at age \( x \).

Adults start with zero assets (i.e. \( a_{i,x_0} = 0 \)) and are borrowing constrained (i.e. \( a_{i,x} \geq 0 \)). The gross labor income at age \( x \) depends on the age-specific productivity \( \epsilon_x \), the aggregate wage per efficiency unit \( w_{i+x} \), and the work effort \( \ell_{i,x} \). Assets held evolves over the life cycle according to

\[
a_{i,x+1} = \begin{cases} 
R_{i+x}^a a_{i,x} + R_{i+x}^b B e q_{i,x} + (1 - \tau_l - \varsigma \tau_{s,i+x}) w_{i+x} \epsilon_x \ell_{i,x} - (1 + \tau_{c,i+x}) c_{i,x} & \text{if } x_0 \leq x < z, \\
R_{i+x}^a a_{i,x} + R_{i+x}^b B e q_{i,x} + b_{i,x}(z) - (1 + \tau_{c,j+z}) c_{i,x} & \text{if } z \leq x < \Omega.
\end{cases}
\]

(10)
where $R_{i+x}^a = (1 + r_{i+x}(1 - \tau_k)) \left( 1 + \frac{\gamma}{p_{i+x}} \right) - \tau_p$ is the after-tax compound interest rate contingent on annuitizing a fraction $\gamma$ of assets held, $R_{i+x}^b = 1 + r_{i+x}(1 - \tau_k) - \tau_b$ is the after-tax compound interest rate on bequest, $Beq_{i,x}$ is the bequest received at age $x$, $\{\tau_b, \tau_l, \tau_p, \tau_e, \tau_c, \tau_s\}$ are the taxes on capital income, labor income, property, bequest, consumption, and social contribution, respectively, with $c$ being the fraction of social contributions paid by the employee, and $b_{i,x}(z)$ is the conditional pension benefit on retirement at age $z$ earned at age $x$.

Similar to the Japanese pension system, we assume that pension benefits are comprised of a full basic pension, $b_{i,x}^b(z)$, and an earning-related pension, $b_{i,x}^\ell(z)$. Provided the supply of labor along the life-cycle, we calculate the pension benefit that our individual claims according to the following formula:

$$b_{i,x}(z) = b_{i,x}^b(z) + b_{i,x}^\ell(z) = \lambda(z) \mu \bar{w}_{i+z} + \vartheta_{i+x} \frac{\psi(z)}{N_b} \sum_{u=z-N_b}^{z-1} w_{i+u} \ell_{i,u}, \quad (11)$$

where $\lambda(z)$ denotes the penalties and incentives for early and late retirement

$$\lambda(z) = \begin{cases} 1 + \lambda_p(z - z_n) & \text{if } z < z_n, \\ 1 + \lambda_r(z - z_n) & \text{if } z \geq z_n, \end{cases} \quad (12)$$

where $\{\lambda_p, \lambda_r\}$ are the annual penalty and reward rates, respectively, and $z_n$ is the normal retirement age, $\mu$ is the basic pension benefit to average labor income ratio, $\bar{w}_t$ is the average earnings in year $t$, $\vartheta_t$ is the value of the automatic adjustment factor mechanism in year $t$ introduced to guarantee the sustainability of the public pension scheme, $N_b$ is the assessment period and $\psi(z)$, which is equal to $r_a \cdot z$, is the accumulated accrual rate of the pension benefit, where $r_a$ is the annual accrual rate.

### 2.4 Household heads’ optimal decisions

Conditional on the retirement age $z$, we calculate the household head’s optimal decision recursively using backward induction from age $\Omega$ until age $x_0$. The Bellman’s equation of a household head born in year $i$ at age $x$ is

$$V(a_{i,x}; z) = \max_{c_{i,x}, \ell_{i,x}} \left\{ u(c_{i,x}, \ell_{i,x}; \eta_{i,x}) + \beta \left( p_{i,x+1} V(a_{i,x+1}; z) + q_{i,x+1} u^B(a_{i,x+1}) \right) \right\} \quad (13)$$

subject to (10). The household head’s first-order conditions on consumption and work effort are:

$$\frac{-u_c(c_{i,x}, \ell_{i,x}; \eta_{i,x})}{u_e(c_{i,x}, \ell_{i,x}; \eta_{i,x})} = w_{i+z} \ell_x (1 - \ell_x \bar{w}_x), \quad (14)$$

$$\frac{u_e(c_{i,x+1}, \ell_{i,x+1}; \eta_{i,x+1})}{u_e(c_{i,x+1}, \ell_{i,x+1}; \eta_{i,x+1})} = \frac{\beta R_{i+x+1} p_{i,x+1}(1 + \tau_{cx})}{1 + \tau_{cx+1}} + \frac{R_{i+x+1} q_{i,x+1}(1 + \tau_{cx}) u^B(a_{i,x+1})}{u_e(c_{i,x+1}, \ell_{i,x+1}; \eta_{i,x+1})}, \quad (15)$$

6
where \( 1 - t_{i,x}^E = \frac{1 - \tau_l - \tau_{GW}}{1 + \tau_{GW}} \) is the effective labor income tax of an individual born in year \( i \) at age \( x \). Eq. 14 means that the marginal rate of substitution between leisure and consumption equals the wage rate net of effective labor income tax. Under the current model, Eq. 15 shows that the marginal rate of substitution between present and future consumption increases not only because of the factor \( \beta R_{a_{i,x}} + x_{i,x} + 1 \) but also with higher values of the marginal utility from leaving bequest.

The optimal retirement age condition is

\[
[u_c(c_{i,z^*}, \ell_{i,z^*}; \eta_{i,z^*}) - \beta q_{i,z^*+1}u_B(a_{i,z^*+1}(1 + \tau_{c,z^*}))(1 + \tau_{c,z^*})] w_{i,z^*+1} \epsilon_{z^*} \ell_{i,z^*}(1 - t_{i,z^*}) = u(c_{i,z^*}, 0; \eta_{i,z^*}) - u(c_{i,z^*}, \ell_{i,z^*}; \eta_{i,z^*}).
\]

where \( t_{i,x}^P = \frac{1 - \tau_l - \tau_{GW}}{1 + \tau_{GW}} \) is the effective participation tax, and \( t_{i,x}^{GW} \) is the tax/subsidy rate introduced by Gruber and Wise (1999, 2004, 2007). Eq. 16 shows that individuals optimally retire when the marginal benefit of continue working at age \( z^* \) (left-hand side) equals the marginal cost of working (right-hand side). Notice that, ceteris paribus, the marginal utility of leaving bequest (the second term in brackets) negatively affects the retirement decision through a reduction in the marginal benefit of working. Besides, since continue working at older ages is not increasingly costly for the household head, under the current model the retirement decision is primarily explained by retirement incentives (Gruber and Wise, 1999).

### 2.5 Government

The government runs a two-tier PAYG pension scheme: a basic pension and an earnings-related pension. The total cost of each pension scheme in year \( t \) is:

\[
BP_t = \sum_{x=z}^{\Omega-1} \beta^{k_n} B_{t-x,x}(z) N_{t-x,x+1}, \quad (\text{Basic pension}) \tag{17}
\]

\[
EP_t = \sum_{x=z}^{\Omega-1} \beta^{e_t} E_{t-x,x}(z) N_{t-x,x+1}, \quad (\text{Employee’s pension}) \tag{18}
\]

Each pension scheme follows a different financing mechanism. In particular, a fraction \( \theta_t \) of the total basic pensions claimed in year \( t \) (\( BP_t \)) are financed through contributions, whereas a fraction \( 1 - \theta_t \) is financed through general taxes. On the contrary, the Employee’s pension scheme was originally designed to be fully funded by current contributions. After the reform introduced in year 2004, the future evolution of the social contribution tax rate is cap and an automatic sustainability factor mechanism based on the active population and life expectancy from age 65 is implemented, \( \vartheta_t \). Hence, we assume that any temporary difference between \( EP_t \) and contributions received will be financed through general taxes. The social contribution rate satisfies

\[
\sum_{x=x_0}^{z-1} w_{t} \epsilon_{t-x,x} N_{t-x,x+1} = \theta_t BP_t, \tag{19}
\]

\[
\sum_{x=x_0}^{z-1} w_{t} \epsilon_{t-x,x} N_{t-x,x+1} = EP_t - D_t, \tag{20}
\]
where \(D_t\) is the temporary deficit of the Employee’s pension system. Hence, the
total social contribution tax rate is the sum of that of the basic pension and the
employee’s pension, i.e. \(\tau_{st} = \tau_{kn} + \tau_{et}\).

The government also provides goods and services, denoted by \(G_t\), which are
assumed to be a fixed proportion of output. To finance the public expenditures
and the deficit of the public pension system, the government levies taxes on labor
income (\(T_{lt} = \tau_l L_t\)), capital income (\(T_{kt} = \tau_k A_t\)), bequest received (\(T_{bt} = \tau_b B_t\)), and consumption (\(T_{ct} = \tau_c C_t\)). We assume the
government runs a balanced budget in which consumption taxes finance the gap
between public expenditures and all other tax revenues,

\[ T_{lt} + T_{kt} + T_{pt} + T_{bt} + T_{ct} = G_t + (1 - \theta_t)BP_t + D_t. \tag{21} \]

### 2.6 Equilibrium

Given \(\{\Gamma_t, \delta_t, L_t, N_t\}_{t=t_0}^T\), a recursive competitive equilibrium with transfers
is a set of household policy functions \(\{c_{t,x}, \ell_{t,x}, a_{t,x}, z\}_{x=x_0}^\Omega\), familial transfers
\(\{Beq_{t,x}\}_{x=x_0}^{\Omega-1}\) over \(t \in \{t_0, \ldots, T\}\), government policy function \(\{G_t, \tau_k, \tau_p, \tau_b, \ldots, \tau_{ct}, \tau_{st}, \mu, \lambda(z), N_b, \psi(z), \theta_t\}_{t=t_0}^T\), and factor prices \(\{r_t, w_t\}_{t=t_0}^T\) such that:

- Household policy function given equals the sum of inheritances received:
  \[ \sum_x Beq_{t-x,x}N_{t-x,x+1} = \sum_x q_{t-x,x}a_{t-x,x}N_{t-x,x+1} \tag{22} \]

- Factor prices equal their marginal productivities, so that Eqs. 7 and 8 hold.

- The government’s budget constraints (19), (20), and (21) are satisfied in
each period.

- The stock of capital and effective labor input are given by
  \[
  K_t = \sum_{x=x_0}^\Omega a_{t-x,x}N_{t-x,x+1}, \tag{23}
  \]
  \[
  L_t = \sum_{x=x_0}^\Omega \ell_{t-x,x}N_{t-x,x+1}. \tag{24}
  \]

- The commodity market clears:
  \[
  Y_t = C_t + G_t + I_t, \tag{25}
  \]
  where \(C_t = \sum_{x=x_0}^\Omega c_{t-x,x}N_{t-x,x+1}\) is the aggregate consumption in year \(t\).
3 Data, calibration, and matching

3.1 Demography

Similar to Sanchez-Romero (2013), we use three demographic methods to reconstruct the Japanese population from 1850 up to now: the inverse projection, generalized inverse projection, and the stable population theory (Lee, 1985; Oeppen, 1993; Lotka, 1939). By combining these three demographic methods i) we derive an initial stable population that evolves consistently with the actual population data (see Fig. 1), ii) we derive age-specific fertility rates \( f_{i,x} \) and conditional survival probabilities \( p_{i,x} \) for each cohort that are used to reconstruct the monetary and time cost of childrearing \( \eta_{i,x} \), see Fig. 2, and iii) we derive the demographic relationships needed to calculate the familial transfers (i.e. parenthood, widowhood, number of offspring, number of surviving siblings, etc.). Demography from year 2010 onwards are based on mortality rates calculated using the Lee-Carter method (Lee and Carter, 1992) and age-specific fertility rates from Ogawa et al. (2010).

Data on population size, births, and deaths for the period 1872-2009 are collected from the data based for Historical Statistics in Japan, Statistics Bureau, Ministry of Internal Affairs and Communications.\(^1\) Life expectancy (at birth) data for the period 1947-2009 are downloaded from the Human Mortality Database (2012). Age-specific fertility rates (ASFR) from 1924 to 2004 are taken from the Statistics Information Department, Minister’s Secretariat, Ministry of Health, Labour and Welfare, while future age-specific fertility rates come from Ogawa et al. (2010).

Following Lee et al. (2000), the monetary and time cost of childrearing, depicted in Figures 2(a) and 2(b), are calculated as follows:

\[
\eta_{i,x}^c - 1 = \sum_{u=x_0}^{x} \frac{s_{i,u} f_{i,u} s_{i+2-u,x-u,x-u}}{s_{i,x}} \theta_{x-u}^c,
\]

\[
\eta_{i,x}^\ell = \sum_{u=x_0}^{x} \frac{s_{i,u} f_{i,u} s_{i+2-u,x-u,x-u}}{s_{i,x}} \theta_{x-u}^\ell,
\]

where \( \theta_{x-u}^c \) is the adult’s consumption equivalence scale that equals 0.4 for children under age of 5 and increases linearly from age 5 to reach 1.0 at age 20\(^2\) \( \theta_{x-u}^\ell \) is the fraction of time devoted to taking care of a child of age \( x \) that equals 1 at age 0 and decreases exponentially to reach 0 at age 20. Since individuals leave their parents’ home at age \( x_0 \), we set \( \{\theta_{x-u}^c, \theta_{x-u}^\ell\} \) at zero for all \( x > x_0 \).

In Japan, the number of equivalent adult consumers supported by a household head peaks during the first half of the twentieth century reaching a value of

\(^1\)The data can be downloaded going to http://www.stat.go.jp/english/data/chouki/index.htm.
\(^2\)This is the standard method used in the National Transfer Accounts project (NTA) (Mason and Lee, 2011). For a discussion of alternative methods, see Deaton (1997) and Lee (1980).
2 for the age group 35-45, which correspond to the baby-boom generation. This value implies that during the first half of the 20th century each household head spent supporting their offspring’s consumption needs as much as in her/his own consumption. Similarly, the time devoted to childrearing significantly increased during the first half of the twentieth century for the age group 25-35. For instance, a representative household head had to spend 20% their available time caring for their offspring, which reduces the household head’s potential labor income. After the 1950s, looking at Figure 2, we observe how the persistent decline in fertility freed up monetary and time resources for development. This process is part of the well-known first demographic dividend (Williamson, 2013; Sanchez-Romero, 2013; Kelley and Schmidt, 2005; Bloom and Williamson, 1998) that started in the 1950s and ended in the 1980s in Japan (Ogawa et al., 2011). In the long run, according to the mortality and fertility schedules depicted in Figure 1, household heads are expected to spent one-third of their own consumption in their offspring and an average time of 10% of their available time caring for their children.

Finally, in this article, by using the demographic information derived from the population reconstruction and Eqs (1)-(4), we estimate the average bequest received by an individual born in year \(i\) at age \(x\), which depends on the marriage status of parents and the marriage status of the receiver. Thus, we calculate four possible bequest profiles: a) bequest received at death of first parent, b) bequest received at death of second parent, c) bequest received at the simultaneous death of both parents, and d) bequest received at death of the spouse. The total amount of bequest received by age will depend not only on the demographics but also on the inheritance law and the number of assets held by each adult, which is obtained from our calibrated CGE model.

### 3.2 Economy

We calibrate the model to the Japanese economy using i) SNA data from 1885-2010, published by Department on National Accounts, Economic and Social Research Institute, Cabinet Office (2012), ii) consumption and labor income profiles for years 1984, 1994, and 2004 taken from Ogawa et al. (2011), and iii) the average bequest in year 2009 calculated from the Japanese Study on Aging and Retirement (JSTAR).\(^3\)

For comparability reasons with the previous literature, we assume a generalized version of the period utility from consumption and leisure used by Braun et al. (2009) for Japan:\(^4\)

\[
\begin{align*}
\bar{u}(c_{i,x}, \ell_{i,x}; \eta_{i,x}) &= \left[ \left( \frac{c_{i,x}}{\eta_{i,x}} \right)^{\phi_c \eta_{i,x}^{c}} \left( 1 - \ell_{i,x} - \eta_{i,x}^{f} \right)^{1-\phi_c} \right]^{1-\frac{1}{\sigma}} - 1 \right] / \left( 1 - \frac{1}{\sigma} \right) (28)
\end{align*}
\]

---

\(^3\)JSTAR was conducted by the Research Institute of Economy, Trade and Industry (RIETI), Hitotsubashi University, and the University of Tokyo. It is a panel data survey comparable to the Health and Retirement Study (HRS), the Survey on Health, Aging and Retirement in Europe (SHARE), and the English Longitudinal Survey on Ageing (ELSA).

\(^4\)The Frisch elasticity for labor supply is \(\frac{1-\frac{1}{\sigma}}{1-\frac{1-\phi_c}{\sigma+(1-\phi_c)(1+\phi_c)(\eta^c-1)}}\).
and the recent utility from leaving bequest $a_{i,x}$ used by Imrohoroglu and Kitao (2012):

$$u^B(a_{i,x}; \eta_{i,x}) = \psi_1 \left[ (\psi_2 + (1 - \gamma)(1 - \tau_b)a_{i,x})^{\phi_c \eta_{i,x}(1 - \delta)} - 1 \right] / \left( 1 - \frac{1}{\sigma} \right).$$  

(29)

The parameter $\phi_c$ represents the utility weight on consumption, $\psi_1$ is the weight on the utility from bequeathing, and $\psi_2$ affects the curvature of the utility from leaving bequest. Parameters $\{\phi_c, \sigma\}$ were chosen so as to have an average Frisch elasticity on labor supply (both at the intensive and extensive margins) of 0.85 (Kuroda and Yamamoto, 2008), which is consistent with Rogerson and Walle nius (2013), and to replicate the capital-to-output ratio from 1885 to 2010 (see Figure 3(a)).\(^5\) The per capita bequest by age is obtained from JSTAR database (Ichimura et al., 2009), a Japanese survey similar to the HRS, SHARE, and ELSA. This survey contains information on the total amount of inheritance (bequest and gifts) received along the lifetime. Thus far, after the two first rounds of the survey, the sample of people who have received bequests in the period between 2007 and 2009 is only 219 out of 3496. Since the sample size is small, we have smoothed the data using the Lowess method (see the solid gray curve in Figure 3(b)) and we have opted for running three alternative scenarios with parameters $\{\psi_1, \phi_c, \sigma\}$ equal to $\{10, 0.42, 0.33\}$ in Scenario I (low bequest motive), $\{50, 0.39, 0.25\}$ in Scenario II (medium bequest motive), and $\{400, 0.36, 0.18\}$ in Scenario III (high bequest motive). We believe that our scenarios I-III covers the most likely bequest profile for year 2009 and hence from now on we consider these scenarios as equally likely. For this reason, the results presented in this article contain all three scenarios.

[Figure 3 about here.]

[Figure 4 about here.]

Capital share $\alpha$ is set to 0.363, based on Hayashi and Prescott (2002). The subjective discount factor is set to 0.99 (Imrohoroglu and Kitao, 2012; Braun et al., 2009; Hurd, 1989). Capital stock ($K$), output ($Y$), and consumption of fixed capital ($CFC$) from 1885 to 2010 are withdrawn from Department on National Accounts, Economic and Social Research Institute, Cabinet Office (2012). Using this information, we derived that the average depreciation rate ($\delta$) during this period is 5%. We calculated the labor-augmenting technological progress by applying the standard formula

$$\ln \Gamma_t = 1/(1 - \alpha) \ln Y_t/N_t - \alpha/(1 - \alpha) \ln K_t/N_t - \ln L_t/N_t, \quad (30)$$

where $L_t$ is quality-adjusted aggregate labor input and $Y_t$ is the GDP net of indirect taxes (Sun, 2006). To construct the quality-adjusted labor input series $L_t$, we combine the age-specific productivity index estimated by Braun et al. (2007), the average hours worked by age-group, and labour force by age group for the period 1968-2006 from the Statistics Bureau, Ministry of International Affairs and Communications. Figure 5 depicts the estimated labor-augmenting

---

\(^5\)Kuroda and Yamamoto (2008) find that the Frisch elasticity on the labor supply at the intensive and extensive margins ranges between 0.7 and 1.0 in Japan, when both males and females are combined.
From 1955 to 1968, it is assumed that $\Gamma_t$ grows at a constant 3%, while before year 1955 and after 2006 we assume an annual growth of $\Gamma_t$ of 1%.

Government consumption to output ratio is set to 12% ($G_t/Y_t$), the average during the period of analysis. The capital income tax rate ($\tau_k$), labor income tax rate ($\tau_l$), property tax rate ($\tau_p$), and the bequest tax rate ($\tau_b$) are calculated using data from the OECD (2012). The main parametric components of the Japanese pension system, summarized in Table 1, are obtained combining information from Sakamoto (2005, 2009). For simplicity, we assume that the automatic sustainability factor algorithm introduced in year 2004 is given by:

$$\vartheta_t = \max (0.5, \vartheta_{t-1})$$

$$= \begin{cases} 
(\frac{L_t}{L_{t-1}}) \cdot 0.997^{\frac{e_t(65)}{e_{t-1}(65)}} - 1 & \text{if } (\frac{L_t}{L_{t-1}}) \cdot 0.997^{\frac{e_t(65)}{e_{t-1}(65)}} - 1 < \frac{w_t}{w_{t-1}}, \\
0 & \text{if } (\frac{L_t}{L_{t-1}}) \cdot 0.997^{\frac{e_t(65)}{e_{t-1}(65)}} - 1 \geq \frac{w_t}{w_{t-1}}, \end{cases} \quad (31)$$

where $e_t(65)$ is the life expectancy from age 65 in year $t$. Notice that in order to avoid an ever decreasing sustainability factor due to a declining labor force, we introduce the assumption that $\vartheta$ cannot be smaller than 0.5. Furthermore, from year 2004 we introduce a maximum social contribution rate for the Employee’s pension scheme ($\tau_{e,t}^s$) starting at 13.58%. Afterwards, the maximum contribution rate is assumed to increase 0.354% every year until 2018, reaching a maximum of 18.3%.

Table 2 summarizes the main baseline model economy parameters.

4 Estimation of the historical bequest

In Section 3 we have shown that our model is capable of reproducing historical capital-to-output data as well as consumption, labor income, and bequest profiles for several years. Therefore, we are confident that our CGE model can contribute to give further insight on the historical evolution of the bequest to output ratio and the importance of bequests on the existing capital stock in Japan.

To the best of our knowledge, this is the first article using a CGE model that analyze the historical evolution of bequest in Japan. However, for the 1980s and 1990s we can find several studies estimating bequests (Shimono and Ishikawa, 2002; Campbell, 1997; Barthold and Ito, 1992; Dekle, 1989; Hayashi, 1986). In Japan, most of the literature show that bequests play a minor role explaining the existing national wealth during the period they analyzed (Campbell, 1997; Barthold and Ito, 1992; Dekle, 1989; Hayashi, 1986), except for Shimono and Ishikawa (2002) that estimate that bequests might represent 30 to 40 percent of national wealth for the period 1986-1994. The results obtained by Shimono and
Ishikawa (2002), however, are overestimated due to the fact that they calculate total bequests multiplying the average bequest left by a deceased male by the total population at risk, instead of multiplying by the deceased male population. Thus, if one uses the latter variable, total bequests becomes 8-13% of national wealth. Nevertheless, this result is still upward biased because the last age-group interval used for their calculations (age 65 and over) is too young for the Japanese population.

Recently, using observed bequests and gifts tax data from France, Piketty (2011) shows that the flow of inheritance to output ratio follows a pronounced U-shaped pattern during the twentieth century. In Japan, Figure 6 shows that all simulated bequest to output ratios follow the same U-shaped pattern. The difference between our results and those of Piketty’s is due to the fact that he also includes gifts (inter-vivos transfers), which account on average for 50% of the total inheritance wealth transmission in France (Piketty, 2011, p. 1104). Therefore, our results suggest that the level of bequest to output ratio in Japan is pretty similar to that in France.

According to Piketty (2011), the observed U-shaped pattern is due to three components: i) the crude death rate (CDR), ii) the aggregate wealth-output ratio \( \frac{K_t}{Y_t} \), and iii) the ratio between the average wealth of the deceased adults and the average wealth of the living adults \( \mu_t \).

The multiplication of the three components gives the annual bequest flow as a fraction of output. Thereby, our simulations suggest that bequest represented between 4.2% and 6% of output in year 2000 and it will reach between 6.8% and 13.2% of the output by year 2100.

\[ \frac{B_t}{Y_t} = \frac{\sum_x q_{t-x,x} a_{t-x,x} N_{t-x,x+1}}{Y_t} = \frac{\sum_x q_{t-x,x} a_{t-x,x} N_{t-x,x+1}}{\sum_x a_{t-x,x} N_{t-x,x+1} Y_t} = \frac{\sum_x q_{t-x,x} N_{t-x,x+1}}{\sum_x N_{t-x,x+1}} \cdot \frac{\sum_x q_{t-x,x} a_{t-x,x} N_{t-x,x+1}}{\sum_x q_{t-x,x} N_{t-x,x+1}} \cdot \frac{K_t}{Y_t} = CDR_t(x_0) \cdot \mu_t \cdot \frac{K_t}{Y_t}. \]
To analyze the importance of bequests on the existing wealth in Japan, we extend the two competing definitions of the share of inheritance in aggregate wealth accumulation proposed by Kotlikoff and Summers (1981), Modigliani (1986, 1988), and Kotlikoff (1988) to non-stable demographic structures.\(^9\) Recall that the difference between the two competing definitions stems from the capitalization of past bequests. Let the total wealth inherited up to age \(x\) by an individual of cohort \(i\) be

\[
\tilde{T}_{i,x} = \sum_{s=0}^{x} \left( \prod_{z=s}^{x} p_{i,z} \right) \text{Beq}_{i,s}. \quad \text{(Modigliani)} \quad (32)
\]

\[
T_{i,x} = \sum_{s=0}^{x} \left( \prod_{z=s}^{x} R_{i,z}^{a} p_{i,z} \right) \text{Beq}_{i,s}. \quad \text{(Kotlikoff)} \quad (33)
\]

Eq. 32 stands for the value of the stream of bequests received up to age \(x\) and not yet bequeathed, while Eq. 33 is the value of past bequests capitalized until age \(x\) and not yet bequeathed.\(^{10}\) For a standard mortality schedule, total wealth inherited increases the younger the individual receives the bequest and the greater is the difference between the age of receiving bequest and the age of giving bequest. Table 4 reports average ages of bequeathing (denoted by \(\bar{D}\)) and receiving bequest (denoted by \(\bar{I}\)) derived from our CGE model for the three scenarios. Since individuals with bequest motive do not completely deplete their assets before reaching the maximum age, the difference between the average age of bequeathers and the average age of heirs is greater in Scenario III (22.7 years) and progressively declines as the strength of the bequest motive diminishes (22.2 years in Scenario II and 21.4 years in Scenario I). During the period 1850-2100, we can observe a continuous and parallel increase in both \(\bar{D}\) and \(\bar{I}\) of 28 years.

Adding the total inherited wealth across age we obtain the aggregate inherited wealth in year \(t\)

\[
\tilde{T}_t = \sum_{x=0}^{\Omega-1} \tilde{T}_{t-x,x} N_{t-x,x}, \quad \text{(Modigliani)} \quad (34)
\]

\[
T_t = \sum_{x=0}^{\Omega-1} T_{t-x,x} N_{t-x,x}. \quad \text{(Kotlikoff)} \quad (35)
\]

Figure 7 shows our results for the non-capitalized and the capitalized bequest as a fraction of aggregate wealth for Japan from year 1850 to 2100. Applying the definition proposed by Modigliani (1986, 1988), we observe that the non-capitalized bequests could be between 60-70% of the aggregate wealth during the second half of the 19th century (see Figure 7(a)). Then, non-capitalized bequest progressively declined during the 20th century bottoming out around 25% of the aggregate wealth. In the twenty-first century, however, our simulations suggest

---

\(^9\)In Demography a stable population differs from a stationary population in that the latter has zero growth rate, while both are subject to unchanged fertility and mortality rates.

\(^{10}\)If people die at age \(D\), the number of years between the age at death and when individuals inherit is \(H\), the rate of return is \(r\), and the economic growth rate is \(g\), then Eqs. 32-33 are equivalent to those of Piketty (2011), Modigliani (1988), and Kotlikoff and Summers (1981).
that non-capitalized bequest will again increase up to 40-70% of the aggregate wealth. This result supports the hypothesis that bequest will become important for aggregate wealth accumulation in the twenty-first century (Piketty, 2011).

The share of capitalized bequest to aggregate wealth was around 200-250% in the last half of the 19th century and started to drop around the first quarter of the 20th century (see Figure 7(b)). Then, it bottoms out to values lower than 100% at the end of the 20th century, similar to the 80% reported by Kotlikoff and Summers (1981) in the U.S. for the 1960s-1970s. Interestingly, the size and shape of the decline in the share of capitalized bequest to aggregate wealth, that we obtained for Japan, looks also similar to that of France, although with a time lag probably due to the later entrance of Japan into the demographic transition.

Notice, however, that according to Figure 7(b) capitalized bequest will represent a much lower share of aggregate wealth in the 21st century, in contrast to the result obtained using Modigliani’s definition. With these results we do not pretend to contribute to the Kotlikoff-Summers-Modigliani controversy. Instead, we take our results using $\bar{T}_t$ and $T_t$ as likely minimum and maximum values for the share of bequests in aggregate wealth, which still suggest that bequest played an important role in the aggregate wealth accumulation during the 19th century, however we cannot claim that this will be the case in the 21st century.

In the next section, we study in more detail how bequest is distributed over the lifecycle and whether bequest or labor income will play a major role for the future accumulation of assets.

5 Per capita bequest and the capital stock

5.1 The distribution of per capita bequest

The combination of the population reconstruction and the CGE model allows for computing per capita bequest profiles for each year in a realistic fashion. Here we explain how mortality and fertility changes the shape of the average bequest received along the lifecycle.

In our baseline model, we consider individuals share the bequest between the surviving parent and the eligible siblings (i.e. adult siblings). In particular, based on the Japanese Civil Code, we assume that 50% of the bequest goes to the surviving parent and 50% is equally distributed among the adult siblings. In case both parents die or the second parent dies, 100% of the bequest is inherited among the adult siblings. As already mentioned in Section 2.1, we distinguish four bequest profiles: 1) the bequest received from the death of the first parent, 2) bequest received from the death of the second parents, iii) bequest from the simultaneous death of both parents, and iv) the bequest received from the spouse.11 Realize that since we analyze a representative individual of each cohort, the per capita bequest received equals the sum of the four bequests profiles; otherwise the first three profiles should be mutually exclusive.

11 In this paper, for the sake of saving space, we do not report the bequest from the simultaneous death of both parents given its low probability.
Table 5 shows the decomposition of per capita bequest received from year 1850 to 2100. The dramatic demographic changes occurred during the 20th century greatly influenced the family composition. For instance, before the year 1950, people expected to receive the first bequest, from the death of their first parent, in their early 30s and seven years later from the second parent (see the first two columns ‘average age’ in Table 5). Consequently, it was likely that an individual of age 40 did not have any parent alive. In addition, before year 1950 individuals became widow/er in their mid-50s. After the year 1950, the per capita bequest profile shifts toward older ages due to the rapid increase in life expectancy. By year 2000, the first parent was expected to die when individuals were 44 years old, and both parents were dead, on average, when individuals reached their mid-50s. Widowhood was postponed up to the early 70s, almost 20 years later than in the 1850s. By year 2100, and assuming that life expectancy does not increase from 2060 onwards (see Figure 6), the first bequest will be expected in the mid-50s and the death of the second parent will occur, on average, close to retirement. Widowhood will happen in the mid-80s.

Despite the fact that the total fertility rate (TFR) were between 3.5 and 4 before the year 1850, the average number of adult siblings at death of the first parent was 2 (see the first column ‘average number of siblings’ in Table 5). With the rise of fertility and the decline of mortality, the number of eligible siblings increase over 3 from year 1925 to 1975, substantially reducing the average per capita bequest received. From year 1975 to 2100, the average number of adult siblings decline up to 1.38. Not surprisingly, this value is close to the TFR since the risk of dying before age 50 will be very low.

Interestingly, by adding the average bequest received for the different bequest profiles reported in Table 5, we obtain the average per capita bequest relative to the average labor income between ages 30-49 (see Figure 8). This new measure is interesting because it is less sensitive to changes in the labor supply than output. Comparing Figure 6 to Figure 8 we observe in all three scenarios that per capita bequest relative to the average labor income for prime age workers do not increase as much as the bequest-to-output ratio during the twenty-first century. For instance, the Scenario I in Figure 8 suggests that labor income will continue playing a more important role for the well-being of individuals than bequest along the 21st century, while the opposite could be understood looking at Figure 6. Nevertheless, the difference between the two figures diminished with the strength of the bequest motive. The intuition for the difference between figures 6 and 8 is simple. Changes in the population distribution has a bigger impact on output than on the stock of capital. Specifically, an increase in life expectancy followed by a decrease in fertility below replacement level (i.e. population aging) leads to a faster decline in output than in wealth and, as a result, the ratio of bequest to output rises. This is because while the decline in the supply of labor affects both output and the stock of capital, individuals increase their savings for retirement motive.

It is worth noting that if there is a preference for giving the estate to a specific gender, there will be approximately one male and one female.
In sum, we believe that, in Japan, the importance of bequest and labor income in shaping the accumulation of assets during the 21st century will be the same as in the second half of the 20th century.

5.2 Implications of the per capita bequest profile on the capital stock

In the baseline model we have assumed, yet realistically, that 50% of the bequest goes to the surviving spouse and 50% to children. Recall that the Japanese civil law presumes that one-half of the state goes to the spouse and each child receives an equal share of the remainder. In other countries, like the United States, there is no legal provision designating neither the number of heirs or how much of a bequest is to be given. In Sweden, there is limited testamentary freedom and the surviving spouse has free disposal of the deceased state but not the right to bequeath it, which normally goes to children.

The large variety of bequest laws across countries generally reflects different social norms and specific historical and economic circumstances, which we abstract from in this article. Taking this into consideration and given our model set up, it makes sense to receive the bequests early in life in order to reap the benefits of the return of the inheritance during a longer period and, simultaneously, increase savings and the capital stock (see Eq. 33). To analyze the economic consequences of this policy option, we run two additional counterfactuals in which the government announces that from year 2015 the shares of the inheritance given to the spouse and children will change. Specifically, the new shares are: i) 100% of the state goes to children and zero to the spouse (hereinafter labeled, counterfactual I) and ii) 100% of the state goes to the surviving spouse; and, in the case that there is no spouse, the inheritance goes to children (hereinafter labeled, counterfactual II).

Figure 9 shows the distribution of the per capita bequest received and its impact on the capital-to-output ratio from 1985 to 2100 under the three different scenarios. The baseline scenarios are depicted in black, while the counterfactuals are depicted in dark gray (counterfactual I) and light gray (counterfactual II). At a first glance, we see that giving all the bequest to children (spouses) raises (diminishes) the capital-to-output ratio in all scenarios (see Figures 9(b), 9(d), 9(f)). This is due to the fact that the difference between the average age of bequeathers, which remains the same, and the average age of receivers increases (decreases) (see Figures 9(a), 9(c), 9(d)). In particular, in year 2015 the average age of receivers becomes 53.2 year (8.4 years more compared to the baseline) in Scenario I, 55.1 years (7.8 years more) in Scenario II, and 56.6 years (7.2 years more) in Scenario III. In contrast, when all the bequest is given to the surviving spouse, the average age of heirs increases 8.2 years (69.8 years old) in Scenario I, 7.5 year (70.4 years old) in Scenario II, and 6.9 years (70.7 years old) in Scenario III.

[Figure 9 about here.]

The result presented in this subsection suggests that with the observed increase in the labor force participation of women, and as long as actual households resemble our simulated households, an internal option for boosting the stock of capital, in order to cope with the rapid population aging, is to introduce a policy that transfers all the estate to children.
6 Conclusion

In this article we have implemented a general equilibrium model with realistic demography to estimate the historical evolution of bequest during the period 1850-2100.

Our simulation results suggest that bequest represented between 8 and 11 percent of the output in the second half of the 19th century. We show how the rapid increase in population was accompanied with rapid changes in the household composition and a progressive decline in the share of bequest on output until the 1970s. By year 2000, the bequest-to-output ratio represented between 4% and 6% of output. However, the rapid aging of the Japanese population will raise the annual bequest flow as a fraction of output up to values between 7% and 13%.

Our historical pattern of the bequest-to-output ratio supports the result presented by Piketty (2011) for France. Nevertheless, we show that the most important variable explaining the U-shaped pattern in Japan is the crude death rate, rather than the evolution of the capital-to-output ratio or the ratio between the average wealth of the deceased and the average wealth of the living.

At the individual level, the recovery of the bequest-to-output ratio up to levels similar to those in the 19th century do not necessarily imply that bequests will become relatively more important than labor income (and thus human capital) on the accumulation of wealth.

- Introduction of the sustainability factor

Note: The table provides the key components of the Japanese pension system, including basic and earning-related pension schemes, with specific parameters such as interest rates, age at retirement, and years of benefit accumulation, before and after specific reforms in 1994, 2000, and 2004.
